Abstract

The presence of fluoride, lithium and carbonate group within hydroxyapatite occurring naturally within the body provides the basis for investigating the sintering ability of co-substituted hydroxyfluorapatites nanopowders for use as biomaterials. $\text{Ca}_{10-x}\text{Li}_x(\text{PO}_4)_6-x(\text{CO}_3)_x(\text{OH})\text{F}$ nanopowders, with x equal to 0, 0.5, 1, 1.5, 2 and 2.5 were prepared using mechanosynthesis and their extensive characterization was realized. Substitution causes contraction of the unit hexagonal cell along the a -axis and elongation along the c -axis, as well as a decrease in the degree of crystallinity of the powders, and an increase of the amounts of unreacted calcium and lithium carbonates. Crystallite sizes and strains, determined by the Halder & Wagner method, remain the same whatever x . Spectroscopic analyses show that B-type carbonated apatite is formed. Annealing at 500°C improves the crystallinity of the apatite phase with low percentages of calcite and lithium phosphate as secondary phases ($x \leq 2$). Transmission electron microscopy observations show that untreated and calcined powders consist mainly of spherical nanoparticles. As-mechanosynthesized $\text{Ca}_9\text{Li}(\text{PO}_4)_5(\text{CO}_3)(\text{OH})\text{F}$ powder, sintered by Spark Plasma

Sintering, densifies in the temperature range of 580 to 650 °C. The crystallite size remains the same than that of the untreated-powder (about 15 nm).

Key words: Mechano-synthesis, Nanoparticles, Hydroxyfluorapatite, Li^+ and CO_3^{2-} substitution, Sintering

1. Introduction

Biomaterials are widely used in the medical field, for example to replace or repair defective hard tissues in the human body. These biomaterials can be divided into four categories: calcium phosphate-based bioceramics, metals and alloys, polymers and materials of natural origin. Bioceramics contain various species commonly found in bones such as Ca^{2+} , PO_4^{3-} , Mg^{2+} , Na^+ , Sr^{2+} , F^- and OH^- ...[1] . Apatite is a large privileged family of calcium phosphates, which has been extensively studied during the last few decades. Their general formula is $\text{M}_{10}(\text{XO}_4)_6\text{Y}_2$ where M is a divalent cation, Y a monovalent anion and XO_4 a trivalent anion. Apatite generally crystallizes in the $\text{P6}_3/\text{m}$ space group (hexagonal lattice) [2].

Apatite are used in various applications particularly in the chemical fertilizer industry [3], in surgery as bone substitutes [4], for fluoride phosphor lamps [5], in pharmacy and in chromatography as a catalyst, for luminescence [6], laser materials, fuel cells [7] and conditioning matrices for nuclear materials [8]. Hydroxyapatite and fluorapatite are the best-known compounds of this family [9]. The flexibility of this structure opens the door to total or partial substitution in the cationic and anionic networks [10]. $\text{Ca}_{10}(\text{PO}_4)_6\text{F}(\text{OH})$ (HFA) is a well-known biomaterial involved in dental and bone formation in the body [11]. When used as an implant, HFA does not cause an inflammatory cellular response. It is naturally present in tooth enamel with F^- ions replacing OH^- up to 50 %. HFA and fluorapatite are also less soluble and more stable than hydroxyapatite [12].

Different synthesis methods have been used to prepare apatite: solid-solid reaction at high temperature [12], precipitation in an aqueous medium [13], hydrolysis by hydrothermal process [14], sol-gel [15] and mechanosynthesis [16]. The powder obtained by each of these methods has different crystallo-chemical and morphological characteristics. Mechanosynthesis is a relatively new method for synthesizing calcium phosphate. It is suitable to prepare nanopowders [17]–[19]. High-energy ball milling presents many advantages for industrial applications where simplicity and high productivity are of paramount importance. The grains undergo successive fracture and welding processes due to repeated shocks during grinding. Planetary mills are powerful tools for synthesizing particles of different sizes and morphologies [20], [21]. Mechanosynthesis is a complex process requiring the optimization of a number of milling parameters to obtain the desired product phase. Coreño *et al* [22] suggested that the advantage of the mechano-synthesis method is that the surface-bound species are disrupted by pressure to improve the thermodynamic and kinetic reactions between the solids. The resulting nanocrystalline HFA are relevant for applications in the biomedical and clinical fields. Indeed, HFA nanostructures can have improved mechanical properties [23], [24]. Significant improvements in the resistance and tenacity of pure HFA have also been obtained through incorporation of different types of additives. However, studies of the properties of lithium-doped apatite are still limited. O. Kaygili *et al* [25] demonstrated that lithium reduces the solubility of HA. Li-substitution increases the thermal stability compared with other cations such as Sr, Mg, and Si [26]–[28]. The insertion of lithium into the hydroxyfluorapatite structure also enhances toughness, osteogenesis-bioactivity and strength. This increase of strength was assigned to the decrease of porosity which results in a more compact and harder structure. Moreover, Mayer *et al* [28] and Popescu *et al* [29] have demonstrated that the absorption of Li^+ by HFA does not change the lattice structure and that lithium causes a decrease in the solubility of carbonated hydroxyapatite which is directly related to biocompatibility.

The incorporation of carbonate groups in the apatite structure is also of particular importance [30], [31]. Carbonate substitution in fluorapatite (FA) and hydroxyapatite (HA) has been studied in depth by radiography of monocrystals, Raman and Infrared (IR) spectroscopies as well as neutron powder diffraction [32]–[34]. Carbonates either are in the tetrahedral phosphate sites (B-type) or in the structural channels located on the hexagonal axis of symmetry (A-type). Each site leads to specific IR and nuclear magnetic resonance (NMR) spectroscopic signatures. Sometimes the carbonate groups are located in both sites (A-B type) [35]–[37]. Despite numerous studies, detailed atomic-scale models of apatite carbonate groups are still under discussion.

Classic high-temperature sintering processes often alter the physico-chemical characteristics, notably surface reactivity and therefore the biological properties of apatite. In addition, they are responsible for the decomposition of non-stoichiometric apatite. Spark plasma sintering (SPS) is a non-conventional sintering technique based on the use of pulsed current, allowing higher heating and cooling rates, lower sintering temperatures and preserving the grains and nanostructures [8]. The consolidation at very low temperature of nanocrystalline apatite thanks to SPS has already been reported and is very promising. Mechay *et al.* [9] and Drouet *et al.* [38] have indeed shown that SPS consolidation limits the physico-chemical modifications of the initial powder and preserves the size of the nanocrystals, leading to compacts with high mechanical strength. Drouet *et al.* [38] observed that with other uni-axial pressure assisted sintering methods, the physico-chemistry and secondary phases are more affected than with SPS.

In this paper, HFA co-substituted with carbonate and lithium ions have been prepared by mechanosynthesis followed by thermal annealing. The powders have been fully characterized by different structural, chemical and morphological techniques before and after annealing. The substituted HFA with $x=1$ (as-mechanosynthesized) was sintered using SPS at 800°C.

2. Experimental procedure

A planetary ball mill (Retsch PM200) was used for the mechanosynthesis of nanopowders of hydroxyfluorapatite. The powder of the starting reagents and 10 mm stainless steel balls were introduced in both 46 mm stainless steel jars. The jars were placed on a 248 mm diameter disc. The mass of the balls is approximately 4 g. For a disc rotation speed of 450 rpm and a jar rotation speed of 900 rpm the injected shock power is about 29 W/g and the cumulative shock energy is about 318 J [39]. The shocks between the wall of the jar, the balls and the powder increase the temperature resulting in the formation of aggregates. Therefore, after a milling time of 26 min, a rest period of 4 min was necessary to limit the formation of these aggregates. The synthesis reaction is as follows:

The as-prepared powders were calcined for 1h at 500°C under air to remove undesirable residual species.

0.3 g of as-prepared powder was also sintered under vacuum by Spark Plasma Sintering (SPS) using a HPD-10 device (FCT System, Germany) with 10 mm diameter graphite molds. A heating ramp of 50°C/min was applied up to 800°C while applying a pressure of 75 MPa for the dilatometric test. Pressure was maintained during the natural cooling too.

The crystalline phase content in the as-prepared and calcined powders was determined by X-ray diffraction (XRD) using a PANalytical XPERT-PRO diffractometer system, operating with the Cu K α radiation ($\lambda = 1.54059 \text{ \AA}$) and with 2θ varying from 10 to 60° with a step of 0.026°. The experimental diffraction patterns were compared with standard maps (ICDD). The Match! Software from Crystal Impact was used to determine the percentages of the various phases and the unit cell parameters of the apatite phase. The crystallite size and strains were calculated using the Halder & Wagner (H-W) method (Eq. 2) [40], [41]. This method considers both the size and strain effects on the

XRD peak broadening and is relevant in case of Gaussian and Voigt profiles. The crystallite size and strain of the NPs are estimated using the H–W equation:

$$(\beta^*/d^*)^2 = \frac{1}{\varepsilon} (\beta^*/(d^*)^2) + (\eta/2)^2 \quad (\text{Eq. 2})$$

where ε is the parameter related to crystallite size, η is the parameter linked to strain, $\beta^* = \beta \cos \theta / \lambda$ and $d^* = 2 \sin \theta / \lambda$ are the reduced coordinates relying on the diffraction angle θ and the wavelength λ . The H-W plots are obtained by plotting $(\beta^*/d^*)^2$ versus $\beta^*/(d^*)^2$. The crystalline size, D , is obtained from the slope (corrected by a factor 4/3) of the fit and the microstrain from the intercept (corrected by 2/5) [18]. The degree of crystallinity of the synthesized samples was determined using (Eq. 3) [42]:

$$\% \text{ Crystallinity} = \left(\frac{0.24}{FWHM} \right)^3 \times 100 \quad (\text{Eq. 3})$$

where FWHM is the full width half maximum value for (002) peak in the XRD pattern of the apatite phase.

Chemical bonding identification was performed in the as-prepared and calcined powders using Infrared and Raman spectroscopies. IR spectra in the mid-infrared region (400 - 4000 cm^{-1}) were obtained using a Spectrum Two 104462 IR spectrophotometer with a diamond ATR setup. For each measurement, 5 mg of sample was deposited on a reflective solid (Tienta SpectRIM). Raman spectra were measured using a Renishaw inVia setup and a 532 nm laser.

Quantitative elemental analysis was carried out by Energy-Dispersive X-ray spectroscopy (EDX) with a JEOL JSM6400F device after deposition on a carbon-coated silicon substrate by evaporating a diluted aqueous suspension. Five zones were investigated for each powder and the average is presented in the following.

The powders were observed by Transmission Electron Microscopy (TEM) in order to estimate the crystal size and compare it with the crystallite size determined by XRD. TEM images were obtained using a JEOL JEM-2100F (at an accelerating voltage of 200 kV) after dropping a dilute suspension on carbon coated copper grids.

The thermal stability of the powders was studied before sintering. ThermoGravimetric Analyses (TGA) of the powders were performed with a TA Instruments Discovery apparatus under an airflow rate of 25 mL/min in a temperature range from 25 °C to 800 °C and at a rate of 5 °C/min. Zeta potential (ζ -potential) and Dynamic Light Scattering (DLS) measurements were obtained with a Malvern Nano ZS instrument (DTS Nano V7.02) at 25 °C. DLS measurements were realized at pH=7.

3. Results and discussions

3.1. Mechanothesized powders

3.1.1. Structural analysis

The X-ray diffractograms of HFA co-substituted with carbonate and lithium with the chemical formula $\text{Ca}_{10-x}\text{Li}_x(\text{PO}_4)_{6-x}(\text{CO}_3)_x(\text{OH})\text{F}$ (with x ranging from 0 to 2.5) are shown in **Fig. 1**. The diffractograms reveal the presence of all the characteristic peaks of the HFA phase (ICDD 04-016-2909) for $x \leq 2$. Additional peaks assigned to unreacted CaCO_3 (ICDD 00-066-0867) and Li_2CO_3 (ICDD 04-010-7186) are also detected. The intensity of the apatite peaks decreases with increasing substitution rates. The peaks of apatite are more intense and narrower for $x < 1.5$. At $x = 2.5$, we notice the total absence of HFA peaks and the presence of unreacted calcite and Li_2CO_3 peaks (Fig. 1). For $x = 2.5$, the diffractogram shows the presence of an amorphous phase, in addition to the calcite phase, which could be the apatite phase.

The apatite cell parameters and the relative amount of the apatite, CaCO_3 and Li_2CO_3 phases, crystallite size, crystallinity and lattice strain are shown in Table 1. Increasing the substitution rate results in a decrease of the a parameter and an increase of the c parameter. The lengths of the carbon-oxygen bonds (1.3 Å) are shorter than those of the phosphorus-oxygen bonds (1.5 Å) and the Li^+ radius ($r(\text{Li}^+) = 0.76$ Å when 6 coordinated) is smaller than the Ca^{2+} one ($r(\text{Ca}^{2+}) = 1$ Å when 6 coordinated). Consequently, the decrease of the a lattice constant can result from the substitution of phosphate

(PO_4^{3-}) groups and Ca^{2+} ions by smaller CO_3^{2-} and Li^+ ions respectively [43]. However, Mayer *et al* [28] observed that a small Li^+ incorporation did not modify the lattice parameters and that small Li^+ incorporation increased with the carbonate substitution rate. The increase of the c parameter is consecutive to the a axis contraction due to the accommodation of the apatite structure to maintain c/a constant [44]. At least, the lattice parameter evolution demonstrates that CO_3^{2-} ions are incorporated into the crystal lattice of HFA. In HA, the substitution of PO_4^{3-} by CO_3^{2-} groups results in a decrease of the a parameter (-0.4%) and a slight increase of the c parameter (+0.06%), in the case of a B-type substitution only [45], [46]. Given the evolution of the cell parameters, it is reasonable to think that the substitution in our HFA is of B-type. The contraction along the a -axis increases with the substitution rate.

The crystallinity of the apatite phase gradually decreased from 49 to 11% with increasing lithium and carbonate content (Fig.1 and Table 1), which is in agreement with previous works [15], [44]. The apatite is non-stoichiometric. The lattice strain remains the same, whatever the substitution and is around 0.40 which is in agreement with Badran *et al* [15].

The amount of the apatite phase are divided by 2 as the substitution rate increases from $x=0$ to 2. The crystallite size is of the order of 18 nm, independently of the substitution rate. Deymier *et al*. [47] have demonstrated by modelling how the carbonate content controlled the apatite crystal growth and favored nanometric apatite crystallites. They obtained a rapid drop off at low carbonate content then followed by a plateau, plateau observed in our case.

Fig. 1. X-ray diffractograms of $\text{Ca}_{10-x}\text{Li}_x(\text{PO}_4)_{6-x}(\text{CO}_3)_x(\text{OH})\text{F}$ powders with $0 \leq x \leq 2.5$

Table 1. Relative amount of apatite, calcite and Li_2CO_3 . Hexagonal cell parameters for the $\text{Ca}_{10-x}\text{Li}_x(\text{PO}_4)_{6-x}(\text{CO}_3)_x(\text{OH})\text{F}$ powders, crystallite size and strains of the apatite phase obtained by the Halder & Wagner method, and crystallinity (%).

x=0	9.372 (2)	6.893 (2)	99.6	0.4	-	19	0.36	49

x=0.5	9.356 (4)	6.901 (3)	94.9	5.1	-	18	0.40	48
x=1	9.353 (5)	6.907 (1)	89.9	7.5	1.6	17	0.42	30
x=1.5	9.347 (1)	6.910 (7)	84.3	11.4	4.3	19	0.36	10
x=2	9.336 (3)	6.914 (5)	51.8	42.3	5.9	17	0.42	11

The IR spectra of the as-prepared samples are shown in **Fig. 2**. The broad absorption bands in the 2500-3700 cm^{-1} range are assigned to the O-H stretching vibration [15], [16]. The IR spectra show all the bands associated to the phosphate groups $(\text{PO}_4)^{3-}$ in the apatite environment: asymmetric stretching (ν_3) located around 1090 and 1041 cm^{-1} , symmetric stretching (ν_1) around 963 cm^{-1} , symmetric bending (ν_4) located between 600 and 560 cm^{-1} and asymmetric bending (ν_2) around 473 cm^{-1} [13]. The appearance of a new low intensity band at about 745 cm^{-1} is assigned to F-OH vibration [16], [20]. Vibration bands of the carbonate groups appear around 842 cm^{-1} and are assigned to the off-plane bending mode ν_2 (in singlet form) and the two elongation antisymmetric modes ν_3 (in doublet form) are observed around 1390 cm^{-1} and 1415 cm^{-1} [36], [37]. The increase in the substitution rate leads to an increase in the intensities of the CO_3^{2-} absorption bands while those of the phosphate groups decrease and become poorly defined. The CO_3^{2-} absorption bands are observed in the $x=0$ powder too. The CO_3^{2-} groups result from either the presence of impurities (CaCO_3) or CO_3^{2-} substitution in the apatite structure. Coreño *et al* [22] have showed that HA obtained by mechanosynthesis using CaCO_3 as precursor of calcium cannot be considered as a non-substituted HA. Spectra of the substituted samples for $x \geq 1$ show also the appearance of new absorption band around 426 cm^{-1} attributed to the vibration mode of the Li-O bond (**Fig. 2b**). This is in accordance with Brooker *et al.* [48] who observed the vibration band of the Li-O bond at about 428 cm^{-1} in a carbonate of lithium.

Fig. 2. IR spectra of $\text{Ca}_{10-x}\text{Li}_x(\text{PO}_4)_{6-x}(\text{CO}_3)_x(\text{OH})\text{F}$ powders with $0 \leq x \leq 2.5$, (a) IR spectra in the 3800-2000 cm^{-1} region, (b) IR spectra in the 2000-400 cm^{-1} region

Fig. 3a shows the Raman spectra of the powders obtained after mechanosynthesis. The observed bands match those reported by Badran *et al.* [15], Antonakos *et al.* [49], and Rehman *et al.* [50]. The most intense band is assigned to the symmetric stretching of the PO_4^{3-} mode (v1) at around 962 cm^{-1} . The peaks located at 429 and 451 cm^{-1} are assigned to the symmetric bending (v2), the one at 1072 cm^{-1} to the v3 asymmetric stretching and those at 585 and 608 cm^{-1} to asymmetric bending (v4) [16]. The very low intensity peaks observed around 387 cm^{-1} correspond to the elongation mode of the Ca-OH bond (v3) [51], [52]. **Fig. 3a** also shows the appearance of peaks attributed to carbonate groups around 1070 cm^{-1} (v1), characteristic of PO_4^{3-} group substitution and around 282 cm^{-1} , 714 cm^{-1} and 1080 cm^{-1} , typical of calcite [53]. Increasing the substitution rate in the apatite structure leads to a decrease in the intensity of the phosphate vibration bands with respect to those of the carbonate groups [50]. A displacement of the characteristic peak (v1) of the PO_4^{3-} groups to lower wave numbers is also detected for $x > 1.5$ (**Fig. 3b**). Penel *et al* [52] observed that the substitution of PO_4^{3-} ions by carbonate ions induces a slight shift towards the low frequencies in the case of B-carbonate apatite (961 cm^{-1}) compared to pure hydroxyfluorapatite HFA (964 cm^{-1}). This shift is unchanged whatever the carbonate substitution rate. They showed also an increase of the widths of all carbonated apatite peaks as the

crystallites become smaller and more distorted when the carbonate amount increased. Thanks to the changes observed in both peak width and peak frequency of the phosphate and carbonate vibration modes, we can reasonably suppose that the substitution is a B-type. A new peak around 1000 cm^{-1} appears for $x \geq 1.5$ (**Fig. 3a**). This band can be assigned to the HPO_4^{2-} group or attributed to the lithium carbonate vibration mode [48]. Unfortunately, the presence of HPO_4^{2-} group cannot be confirmed for sure because the IR bands of HPO_4^{2-} group can be masked by the carbonate band at 870 cm^{-1} or the phosphate band ν_4 .

Fig. 3. (a) Raman spectra of $\text{Ca}_{10-x}\text{Li}_x(\text{PO}_4)_{6-x}(\text{CO}_3)_x(\text{OH})\text{F}$ powders with $0 \leq x \leq 2.5$, (b) the symmetric stretching of the PO_4^{3-} mode (ν_1) of powders

3.1.2. Thermal analysis

Thermogravimetric analyses of the as-synthesized powders are presented in **Fig. 4**. They were performed to study the thermal stability of the samples prepared with different substitution rates. The overall losses are 10.6% ($x=0$), 15.5% ($x=0.5$), 17% ($x=1$) and 16% ($x=1.5$). All the thermograms (for $x > 0$) have at least four mass losses. Their magnitudes depend on the substitution rate. Physisorbed water was eliminated below 100°C . The first mass loss observed at $100\text{-}200^\circ\text{C}$ corresponds to the

departure of chemisorbed water and is about 5% ($x=0$), 6% ($x=0.5$), 4% ($x=1$) and 3% ($x=1.5$). The second loss, of the order of 4% ($x=0$), 5.5% ($x=0.5$), 8% ($x=1$) and 7% ($x=1.5$) located around 200-500°C is attributed to the departure of lattice water, residual NH_4^+ and HPO_4^{2-} species [54]–[56]. Most of the lattice water is related to carbonate ions [54]. The third mass loss observed around 500-750°C depending on x is of the order of 1.6% ($x=0$), 4% ($x=0.5$), 5.0% ($x=1$) and 5.5% ($x=1.5$). It is tentatively assigned to the departure of carbonates and the release of CO_2 [57], [58]. Given that the decomposition temperatures of calcite and lithium carbonate (present as secondary phase in the samples) are above 625°C [59] and 730°C respectively, the release of CO_2 at a lower temperature correspond to the apatite decarbonation. Substitution of fluoride ions in A sites lowers the temperature of decarbonation of B-type apatite down to 500°C [60], [61]. The decarbonation temperature is strongly dependent on the chemical composition. Zyman *et al.* [61] suggested that the removal of carbonate from the apatite structure occurs at temperatures between 550 and 750 °C depending on the carbonation rate. The mass loss is theoretically about 3.1% ($x=0.5$), 6.4% ($x=1$) and 9.9% ($x=1.5$). Considering the mass loss differences between experiment and theory, the decarbonation process can be considered partial for the two highest substitution rates or the substitution rate is not as high as expected in the as-mechanosynthesized powders. Above, the mass loss can be explained by the partial decomposition of HAF apatite and/or secondary phases [62], [63].

Fig. 4. TGA and DTG curves of $\text{Ca}_{10-x}\text{Li}_x(\text{PO}_4)_{6-x}(\text{CO}_3)_x(\text{OH})\text{F}$ powders with $0 \leq x \leq 1.5$

3.2. Calcined powders

Since substituted HAF starts to decompose at temperatures close to 500°C , we have chosen to limit the duration of calcination to 1h at 500°C to improve the crystallinity of the powder.

3.2.1. Structural analysis

The XRD diffractograms of the powders calcined at 500°C in air for 1 hour are shown in **Fig. 5** and the results of the structural analyses are presented in **Table 2**. The apatite lines are more intense and thinner than in **Fig. 1**. The diffractograms also show the appearance of additional peaks for substitution rates larger than 1. Calcium carbonate (ICDD card n°00-066-0867) is observed for $x \geq 1$ whereas it was present in all the as-mechanosynthesized powders. Its proportion is also diminished (6% against 42% for $x=2$). The amount of calcite increases drastically for $x=2.5$. Lithium phosphate (Li_3PO_4) (ICDD card n° 00-025-1030) appears from $x=1.5$, in proportions close to those of the lithium-based compound (Li_2CO_3) detected in the as-mechanosynthesized powders. This is probably related to the saturation of the solid solution for $x \geq 1$ [15]. However, the drastic decrease of the lithium carbonate amount tends to prove that a large part has been incorporated in the apatite structure. Then, the substituted phosphate groups react with Li^+ to form Li_3PO_4 . For $x=1$, the disappearance of lithium carbonate and the absence

of lithium phosphate tend to prove that Li^+ has been incorporated in the apatite structure after the annealing at 500°C .

Fig. 5. X-ray diffractograms of $\text{Ca}_{10-x}\text{Li}_x(\text{PO}_4)_{6-x}(\text{CO}_3)_x(\text{OH})\text{F}$ powders with $0 \leq x \leq 2.5$ calcined 1 h at 500°C under air

Table 2 indicates the variation of the cell parameters as a function of the substitution rate. The decrease of a and the increase of c as a function of x , as observed for untreated samples, is compatible with the preservation of the carbonated B-type apatite. However, the new cell parameter values (higher for a and lower for c than for untreated samples) confirm that decarbonation has occurred during the annealing at 500°C . The crystallite size determined by the Halder & Wagner method (D_{XRD}) for each composition was between 31 and 48 nm. The crystallite size of the calcined powders is one and a half to two and a half times greater than that of the as-mechanosynthesized ones. The crystallite size is

around 45 nm for all the carbonated apatites and of about 30 nm for $x=0$. For the highest substitution rates, the enhanced diffusion ensured by non-stoichiometry is annihilated by the decarbonation which starts earlier. After calcination, the crystallinity of the powders is improved. The value of the crystallinity is between 84 and 42 % for x varying from 0 to 2. For x greater than 0, the strain value remains almost unchanged (around 0.10-0.20). With the increase of the substitution rate of lithium and carbonates, in both anionic and cationic sites, the variation of lattice deformation is low. This can be explained by the fact that the sizes of lithium and carbonate are smaller than the calcium and phosphate groups, so the lattice strain varies slightly.

Table 2. Relative amount of apatite, calcite and Li_3PO_4 . Hexagonal cell parameters for the $\text{Ca}_{10-x}\text{Li}_x(\text{PO}_4)_{6-x}(\text{CO}_3)_x(\text{OH})\text{F}$ powders calcined 1h at 500°C under air, crystallite size and strains of the apatite phase obtained by Halder & Wagner method, and crystallinity (%).

The infrared absorption (IR) spectra of the calcined powders are shown in **Fig. 6**. In comparison with untreated powders (**Fig. 2**), the broad bands between 2500 and 3700 cm^{-1} , attributed to water molecules adsorbed on surfaces, disappear. After calcination, the three bands of phosphate (ν_1 , ν_3 and ν_4) and the two bands of carbonate (ν_2 and ν_3), as well as that of the OH-F bonds located around

745 cm^{-1} have decreased in width. The frequency values of the carbonate group bands (in the doublet form) indicate that the carbonation is still of B-type [64].

Fig. 6. IR spectra of $\text{Ca}_{10-x}\text{Li}_x(\text{PO}_4)_{6-x}(\text{CO}_3)_x(\text{OH})\text{F}$ powder with $0 \leq x \leq 2.5$, calcined for one hour at 500°C under air

The Raman spectra in **Fig. 7** show almost the same characteristic bands observed in **Fig. 3** before annealing. The band at around 1000 cm^{-1} assigned to HPO_4^{2-} and/or a lithium carbonate vibration mode has disappeared. Indeed, HPO_4^{2-} reacts with CO_3^{2-} in B-sites above 400°C [52] and the XRD results have shown the absence of lithium carbonate in the calcined powders. The band of the phosphate group (ν_1) is more intense and thinner from $x=1$. The relative intensities of the phosphate and carbonate groups (at 960 cm^{-1} and 1070 cm^{-1} respectively) have evolved, suggesting that a partial decarbonation has occurred [15], [44]. The relative intensities of the phosphate and carbonate groups

(at 960 cm^{-1} and 1085 cm^{-1} respectively) reverse from $x=1.5$, in good agreement with the decrease of calcite amount in the samples.

Fig. 7. The Raman spectra of all $\text{Ca}_{10-x}\text{Li}_x(\text{PO}_4)_{6-x}(\text{CO}_3)_x(\text{OH})\text{F}$ samples calcined 1h at 500°C under air

3.2.2. Chemical and morphological study

A chemical analysis was performed for the $x=0$ and $x=1$ samples to determine the calcium/phosphorus atomic ratio and the lithium and carbonate substitutions. Elemental analysis by EDX reveals the presence of calcium, phosphorus, oxygen and fluorine for substituted and unsubstituted apatite (**Table 3**). It should be noted that the steel jars and balls used for grinding are sources of iron contamination of the powder. A low contamination (between 0.3 and 0.4% of Fe) resulting from the shocks between the jar wall, the powder and the balls was detected [16]. Detection of lithium and carbon by EDX is of course difficult. A very good agreement between the atomic percentage of the different elements determined from these spectra and those introduced *via* the initial

powders was observed (see **Table S1**). The calcium to phosphorus ratio (Ca/P) increases with the substitution of pairs (Ca^{2+} , PO_4^{3-}) by (Li^+ , CO_3^{2-}), as expected. This increase is compatible with over-stoichiometric B-type carbonated HFA [65]. However, for the untreated sample with $x=0$, it can be assumed that at the beginning of the reaction an amorphous calcium phosphate is formed, with a Ca/P ratio close to 1.5 [66].

Table 3. Atomic percentages of the chemical elements present in untreated and calcined at 500°C of $\text{Ca}_{10-x}\text{Li}_x(\text{PO}_4)_{6-x}(\text{CO}_3)_x(\text{OH})\text{F}$ powders for $x=0$ and 1 determined by EDX

	Untreated sample		Calcined sample at 500°C	
Substitution rate	x=0	x=1.0	x=0	x=1.0
Oxygen	57.1 (5)	64.2 (3)	61.6 (4)	61.6 (1)
Fluorine	3.5 (2)	2.4 (4)	2.9 (1)	2.6 (4)
Phosphorus	14.5 (2)	11.9 (2)	12.9 (2)	12.3 (3)
Calcium	22.3 (4)	21.8 (4)	22.1 (3)	21.7 (1)
Ca/P	1.54	1.83	1.71	1.76

Recent work has shown that apatite compounds with appropriate morphological characteristics have better performance in biomedical applications. To better understand the effect of mechanochemical processes on the morphology of the synthesized nanopowder, TEM analyses were conducted. **Fig. 8a** shows the TEM and HRTEM images of the sample $x=0$ as-mechanosynthesized and **Fig. 8b** shows the TEM and HRTEM micrographs of sample $x=1$ calcined at 500°C.

(a)

(b)

Fig. 8. TEM and HR-TEM images of unsubstituted HFA (a) $x=0$ untreated, (b) $x=1$, calcined at 500°C for 1 hour

All the microstructures consist of micrometer-scale aggregates made of nanocrystalline crystallites. Similar morphologies and sizes are observed for substituted and unsubstituted powders, both untreated and calcined. The TEM images indicate that the particles are nanometric in size and

almost spherical. During the milling process, particles have a strong tendency to aggregate as demonstrated by DLS analysis (**Table S2**). Recent work has reported that when two adjacent primary particles collide, coalescence can occur if the two particles have the same crystallographic orientation. Since the secondary particles are very small, it is reasonable to assume that they continue to collide and coalesce, which lead to aggregation [24], [65]. High-resolution TEM (**Fig. 8a** and **8b**) show that grains are in fact an assembly of nano-crystallites, in accordance with XRD results (**Table 1** and **Table 2**). These images also show the very good crystallinity of the samples. Mean crystallite size observed by TEM, around 50 nm for the sample $x=1$ treated, is in agreement with XRD results. Nevertheless, some particle diameters are higher (**Fig. 8b**), proving a relative large crystallite size distribution, which is typical of mechanosynthesized powder [18].

Fig. S1. shows the zeta potential versus pH curves for HFA samples for $x=0$ and 0.5 (untreated and calcined). Since synthesized samples dissociate at $\text{pH} < 6$, the measurements took place at $\text{pH} \geq 6$. Co-substituted HFA particles have a surface charge that can vary depending on the pH or other adsorbed species in an aqueous medium. Indeed, the surface of hydroxyfluorapatite displays amphoteric properties due to specific adsorption of H^+ and OH^- , leading to different species at surface, such as $\text{Ca-OH}/\text{Ca-OH}_2^+$ or $\text{P-O}^-/\text{POH}$ [67]. The higher the zeta potential of the particles, the greater the tendency of the particles to repel each other, which promotes dispersion [67], [68]. All the curves clearly indicate that the zeta potential values are negative for $\text{pH} \geq 6$ and become larger in absolute value when pH increases, this is in agreement with previous measurements on hydroxyapatite [68]. The differences in absolute value, between the samples at a given pH, may come from adsorption or desorption of the different ions present in the structure and so at the surface: phosphate, calcium, lithium and carbonate ions [68].

The hydrodynamic diameters determined thanks to DLS measurements (D_H) for the powders untreated and calcined at 500°C show that the synthesized powders are aggregated as indicated in **Table S2**. It is in agreement with TEM observations (**Fig. 8**). Indeed, the values are in the micrometric

range while crystallites are in the nanometric range (D_{XRD} , **Table 1** and **Fig. 8**). It seems that an increase of x for the untreated samples leads to larger aggregates as shown in **Table S2**. But for calcined powders the value of D_H seems to decrease with the increase of x . The heat treatment seems to decompose some aggregates, leading to smaller polycrystalline grains size.

3.3. Sintering of a composition of interest

Based on the microstructural characterizations, the substituted samples with $x=0.5$ and $x=1$ have more than 90% of apatite. For this reason, we performed a dilatometric test on the sample with $x=1$. **Fig. 9** shows the temperature-dependent shrinkage evolution of untreated HFA powder ($x=1$) during sintering in an SPS apparatus. The first shrinkage of the order of 0.5 mm at room temperature is the result of cold compaction under 75 MPa. The second shrinkage of 0.4 mm occurs when heating up to about 216°C and corresponds to the departure of water molecules adsorbed on the apatite surface. The third shrinkage of the order of 1 mm occurs in a single step from 580°C and continues until about 650 °C. It corresponds to the sintering of the powder. Densification in HA is governed by the diffusion of hydroxide ions. The partial substitution of hydroxide ions by fluoride ions reduces the mobility of these latter in HFA. Of all the HFA, apatite with a OH:F ratio of 1:1 has the poorest sinterability [60]. Conversely, the substitution of phosphate groups by carbonate groups in HA promotes densification. Lithium seems to have the same effect on sintering. Its insertion in HA activates sintering [69]. Density measurements could have not been performed to confirm the high densification level. Indeed, the sample was broken in small pieces due to its very low thickness (only 0.3 g of powder). However, the dilatometric test showed that densification of such powder could be achieved below 650°C.

Fig. 9. Sintering curve as a function of temperature of as-mechanosynthesized $\text{Ca}_{10-x}\text{Li}_x(\text{PO}_4)_{6-x}(\text{CO}_3)_x(\text{OH})\text{F}$ powder ($x=1$)

Fig. 10 shows the XRD diffractograms of the $x=1$ sample untreated, calcined at 500°C and sintered at 800°C . After sintering, the sample contains apatite and calcite, as after calcination. However, the amount of calcite is higher in the sintered sample (**Table 4**), suggesting that the apatite decarbonation is more pronounced. This decarbonation process is corroborated by the evolution of the cell parameters. However, the application of an appropriate pressure during the SPS cycle can reduce decarbonation significantly [70].

After SPS sintering of the co-substituted hydroxyfluorapatite powder, the crystallite size remains the same than that of the untreated-powder sintered (about 15 nm) (Fig. S2). No grain growth is noticed, contrary to after a calcination (Table 4), this can be explained by the pressure applied during this fast sintering. After the sintering of the powder, the lattice strains rate remain also the same.

Fig. 10. XRD diffractograms of substituted HFA (x=1), untreated, calcined at 500°C and sintered at 800°C

Table 4. Percentages of phases present in substituted HFA powders (x=1) untreated, calcined at 500°C and sintered at 800°C, hexagonal cell parameters, lattice strain and crystallite size (D) of the apatite phase obtained with the Halder & Wagner method and crystallinity rate.

	x=1 untreated	x=1 calcined at 500°C	x=1 sintered at 800°C
Apatite (wt. %) ± 0.1 %	89.9	95.4	84.1
Calcite (wt. %) ± 0.1 %	7.5	4.6	15.9
% Crystallinity	30	79	33
a (Å)	9.353 (5)	9.391 (3)	9.403 (7)
c (Å)	6.907 (1)	6.889 (2)	6.892 (4)

D (± 2 nm)	17	48	13
Lattice strain	0.42	0.11	0.43

4. Conclusion

In the present study, mechanosynthesis was used to synthesize lithium-substituted carbonate hydroxyfluorapatite nanopowders under optimal conditions. Structural and spectroscopic analyses confirm the incorporation of lithium and carbonate into the apatite structure for $x < 2$. The results suggest that the structural features of the obtained samples were influenced notably by the degree of carbonate substitution in the HFA lattice. Substitution causes contraction in the a -axis and elongation of the c -axis as well as a decrease in the crystallinity of the powder. Spectroscopic analyses show that carbonated B-type apatite was obtained. The amount of apatite decreased drastically from 99.6 to 51.8% when the carbonate content increased from $x=0$ to $x=2$, whereas the percentage of unreacted calcite and lithium carbonate increases. It was shown that the removal of carbonate present in the apatite framework occurred at temperatures between 500 and 650 °C. An heat treatment at 500°C allowed to decrease the secondary phases from 48 to 10%, crystallite size and crystallinity were increased. The increased incorporation of lithium into carbonate apatite observed in this study induces a disorder in the carbonate HFA network and allows Li^+ ions to enter the apatite network without altering the crystal structure. According to the results obtained for x greater than 1, the substitution causes a saturation of the solid solution. TEM observations show that untreated and calcined powders consist mainly of almost spherical aggregated nanoparticles. The SPS sintering at temperature below 650°C of the as-mechanosynthesized substituted sample with $x=1$ allowed to maintain the nanometric size of the crystallites and preserve the apatite structure.

Acknowledgments

We would like to thanks the help of N. Geoffroy for XRD analyses, Dr. F. Herbst for EDX investigations, Dr. R. Chassagnon for TEM analyses, and Dr. J. Boudon for TGA analyses.
